Abstract

Atlantic salmon (Salmo salar) is one of the most extensively studied fish species in the world due to its significance in aquaculture, fisheries and ongoing conservation efforts to protect declining populations. Yet, limited genomic resources have hampered our understanding of genetic architecture in the species and the genetic basis of adaptation to the wide range of natural and artificial environments it occupies. In this study, we describe the development of a medium-density Atlantic salmon single nucleotide polymorphism (SNP) array based on expressed sequence tags (ESTs) and genomic sequencing. The array was used in the most extensive assessment of population genetic structure performed to date in this species. A total of 6176 informative SNPs were successfully genotyped in 38 anadromous and freshwater wild populations distributed across the species natural range. Principal component analysis clearly differentiated European and North American populations, and within Europe, three major regional genetic groups were identified for the first time in a single analysis. We assessed the potential for the array to disentangle neutral and putative adaptive divergence of SNP allele frequencies across populations and among regional groups. In Europe, secondary contact zones were identified between major clusters where endogenous and exogenous barriers could be associated, rendering the interpretation of environmental influence on potentially adaptive divergence equivocal. A small number of markers highly divergent in allele frequencies (outliers) were observed between (multiple) freshwater and anadromous populations, between northern and southern latitudes, and when comparing Baltic populations to all others. We also discuss the potential future applications of the SNP array for conservation, management and aquaculture.

Keywords: aquaculture, conservation, population genetics, salmonids, selection, single nucleotide polymorphism

Introduction

Since their divergence from other salmonids, Atlantic salmon (Salmo salar L.) populations have been subjected to strong natural and artificial selection throughout their evolutionary history. These included pronounced habitat shifts associated with glaciations, ‘landlocking’ of fjords or lakes previously open to the sea, as well as various sources of anthropogenic changes (Verspoor et al. 2007). The greatest divergence between Atlantic salmon populations can be seen when comparing the European and North American lineages, which diverged approximately 600 000 years before present (ybp) (King et al. 2007). A more recent fundamental division is seen in populations of nonanadromous fish on both continents, which have evolved independently following ‘landlocking’ of their rivers or fjords (Tessier & Bernatchez 2000; King et al. 2007). In addition, Atlantic salmon inhabit a wide range of habitats with different temperatures, from Spain to the high Arctic (Aas et al. 2011). Atlantic salmon thus represents an ideal species to disentangle the genomic basis of potential parallel evolution at both historic and recent scales.

More recently, there has been a dramatic decline of many wild Atlantic salmon populations due to overfishing, habitat destruction and possibly other indirect causes such as impacts from aquaculture or climatic change (Friedland et al. 2003; Carr et al. 2004; Ferguson et al. 2007; Ford & Myers 2008; Todd et al. 2008). Consequently, wild Atlantic salmon populations have been the focus of international conservation efforts, where population genetic studies have played an important role by genetically inferring phylogeographic patterns and defining evolutionary significant units (ESU) as well as management units (e.g. Vasmépäi et al. 2005; Palstra et al. 2007; Dionne et al. 2008; Tonteri et al. 2009). However, the limited resolution of the available genetic tools has meant that the genomic basis of local adaptation shaped by natural selection is still largely unknown for Atlantic salmon (Fraser et al. 2011). Single nucleotide polymorphism (SNP) arrays represent excellent tools for studying population structure and the effect of natural and artificial selection at the genome level (e.g. The Bovine HapMap Consortium, Gibbs et al. 2009; Willing et al. 2010; many others). For example, for Atlantic cod (Gadus morhua), Bradbury et al. (2010) were able to show parallel clinal association between SNP allele frequencies and water temperatures across the species range, in both North America and Europe. A SNP array for salmon would add substantially to previous efforts by providing managers with an enhanced tool for the definition of ESUs on the basis of neutral and adaptive divergence (Kohn et al. 2006; Primmer 2009). Moreover, it could also improve the resolution of differentiation of genetic stocks and the efficiency of mixed-stock analysis (Gauthier-Ouellet et al. 2009; Griffiths et al. 2010).

Aquaculture of Atlantic salmon is practised on a large scale in both the Northern and Southern hemispheres, and today, it is the most cultivated fish in the western world and the most farmed salmonid worldwide. This expanding industry is recognizing the potential benefits arising from development and application of high-density SNP technologies (Dominik et al. 2010). Indeed, similar resources have been developed for other production species and are proving invaluable for the detection of quantitative trait loci (QTL) underlying economically important traits (Dekkers & Hospital 2002; Daetwyler et al. 2008), strain identification (Suekawa et al. 2010) and to implement marker-assisted selection and genomic selection (Soller 1990; Meuwissen et al. 2001; Dekkers & van der Werf, 2007). Moreover, accidental release and/or the escape of farmed fish into the surrounding wild environment has raised substantial concerns (McGinnity et al. 2003) over the potential genetic impact these fish can have on local wild populations at the genome level (e.g. Hindar et al. 1991; Roberge et al. 2006; Normandeau et al. 2009; Bourret et al. 2011). High-density SNP arrays represent a powerful tool to assess the impacts of escapes on wild populations (i.e. introgression), to trace the source of escapees and to characterize the current status of at-risk wild populations (Karlsson et al. 2011).

The first goal of this study is to describe the development and application of a dense SNP array for Atlantic salmon. Second, we present the most genetically detailed population study of Atlantic salmon whereby 6176 SNPs were genotyped in 1430 individuals from 38 naturally occurring anadromous and landlocked populations collected across the species range. While the main emphasis concerns a description of the population genetic structure of European populations, several North American populations are also included in the assessment. Third, we aim to identify markers and chromosomal regions potentially under divergent selection among populations between and within lineages as well as between anadromous and landlocked populations. Finally, we consider whether potential adaptive divergence is associated with key biological pathways, and environmental patterns of variation.

Materials and methods

Detection of SNPs in EST databases and genome complexity reduction (GCR)

Expressed sequence tags (EST) mining was performed according to Hayes et al. (2007), and using the EST libraries described in this study, a total of 9240 putative SNPs were identified. Limited availability of
DNA excluded the possibility of preparing a Reduced Representation Library (RRL; Alshuler et al. 2000); instead, we describe an approach called genome complexity reduction (GCR) that includes a PCR step to isolate a distributed subfraction of the genome. Genomic DNA was extracted from adipose-fin clips collected from *Salmo salar* using a commercial extraction kit. Samples were digested to completion using Xba1 which, compared to other six-cutter restriction enzymes (RE), produced the most uniform smear of DNA fragments. Synthetic double-stranded DNA adapters containing a PCR-binding site were ligated to the resulting sticky-ended fragments using T4DNA ligase. The resulting product was amplified under standard PCR conditions using a 15-s extension time, which promotes the amplification of fragments up to 1200 bp. The combination of RE cut frequency and amplicon length means that a random fraction of the genome is represented in the final product. Gel analysis of the PCR product revealed an expected smear of fragments and a single region of high intensity, most likely resulting from overamplification of a repeated DNA element. Because repeated DNA can produce false-positive SNPs and consume sequencing capacity, we developed an optional step [reduced GCR (rGCR)] whereby PCR product is separated on a 1% agarose gel and a fragment range (e.g. 500–700 bp), which avoids brighter (repeat) regions being isolated. The typically low DNA recovery requires an additional PCR amplification, which is performed as described above. For SNP discovery, GCR libraries were prepared for individual haploid \( n = 2 \) and diploid \( n = 6 \) samples; in addition, rGCR libraries were prepared for the haploid individuals \( n = 2 \) and a single pool sample containing all diploid samples \( n = 1 \). Haploid fish were produced by fertilizing eggs with irradiated sperm according to Refstie (1983). All biological material originated from Norwegian commercial aquaculture strains (Aqua Gen).

**SNP discovery**

The diploid and haploid GCR libraries were each sequenced twice, while the rGCR diploid pool and haploid samples were sequenced just once using a Genome Sequencer FLX system (Roche). A total of 6,927,968 reads were generated across 19 runs with an average read length of 182 bp. Reads were filtered for repeats and adapter sequence using Lucy (http://lucy.ceh.uvic.ca/repeatmasker/cbr_repeatmasker.py); approximately, 30% of reads were eliminated from the data set because they were identified as repeat sequences. Atlas overlapper (Havlak et al. 2004) was then used to group 1,404,933 reads into 53,769 bins (minimum bin size = 5 reads; average = 26, overlap criteria: 92% identity, minimum read length = 40 bp, min overlap = 36 bp, MaxOverlapSeed = 50). Each set of binned reads was processed by Phrap (Gordon et al. 1998) to generate 77,858 contigs with an N50 contig length of 349bp. Putative SNP discovery was made by aligning individual binned reads back to their matching contigs using Cross_Match (Gordon et al. 1998). Criteria for calling a SNP were a minimum read coverage of 2, and minimum SNP coverage/total coverage \( \geq 0.2 \). The possibility of these SNPs \( n = 17,844 \) being located within unknown (and therefore unmasked) repeats was addressed by blasting the 40 bp flanking each SNP against the contig database. Sequences found to match with 100% sequence identity at any position other than their source were discarded. SNPs were then ranked into categories \( n = 3 \) according to the genotypes of the individual diploid samples sequenced. Category-1 corresponded to SNPs for which there was evidence of homozygous and heterozygous (i.e. AA, BB and AB) allelotypes, category-2 to those with the occurrence of both homozygote allelotypes (AA and BB), and category-3 to those with heterozygote and one homozygote (AB and AA or BB).

Because category-1 SNPs and SNPs with higher read-depth displayed the greatest proportion of polymorphic loci (data not shown), these SNPs were preferentially selected for the array. SNP-assay designability was assessed using Illumina’s online Assay Design Tool (ADT; www.illumina.com) with a required minimum ADT score of 0.7. The final array order included 7021 SNPs originating from GCR, 9240 SNPs from the alignment of EST reads from both European and Canadian material, 58 SNPs from public databases, 169 SNPs detected through BAC-end sequencing (Lorenz et al. 2010) and 63 SNPs detected by mitochondrial DNA resequencing (Karlsson et al. 2010). More details regarding the array development strategy and SNP discovery can be found in supplementary methods (Appendix S1).

**DNA samples**

A total of 1,431 extracted DNA samples sampled between 1977 and 2008 from 38 sample sites (31 from Europe and seven from North America, between 20 and 72 samples per location) were included in this study (Fig. 1; Table 1), thus covering the natural geographical distribution of Atlantic salmon. Five locations in Europe and one in North America represented landlocked populations, while other populations were anadromous.
Genotyping and quality control

Genotyping was performed according to the manufacturer’s instructions using the Illumina infinium assay (Illumina, San Diego, CA, USA). The assay conversion rate was 92% with the final array containing 15 225 SNP assays. Using Illumina’s Genotyping Module software, it was possible to examine each SNPs cluster pattern using data from a set of pedigree samples \((n = 3297)\) provided by a Norwegian aquaculture programme (Aqua Gen AS, Norway) and data from this study \((n = 1430)\). Visual inspection allowed for the classification of SNPs into different categories [i.e. single-locus SNPs, and the more complex paralogous sequence variants (PSVs), and multisite variants (MSVs), arising from genome duplication]. Classification was objectively supported using the program described by Gidskehaug et al. (2011) and is reported in supplementary methods of Lien et al. (2011). Following this (see also Results), a total of 6176 SNP markers were retained in the subsequent analyses of the 1431 population samples, 55% of these were derived from EST, 43% from GCR, and the remaining 2% from the other SNP sources. Because European fish were used in GCR and rGCR, we compared mean observed heterozygosity in both EST and GCR SNPs for European and North American populations to assess potential ascertainment bias. We also compared pairwise population measure of differentiation \((F_{ST})\) for both types of markers. Moreover, within each identified regional genetic groups, we pooled the per population minor allele frequency distribution across loci and compared each regional pooled distribution to each other using the Kolmogorov-Smirnov test in order to further evaluate potential bias in minor allele distribution. Note that we systematically excluded within-population monomorphic markers from the distributions.

Population structure and differentiation

We measured global and per SNP observed and expected heterozygosity within each population. Pairwise genetic differentiation between populations was estimated by \(\theta\) (Weir & Cockerham 1984) using ARLEQUIN 3.5 (Excoffier & Lischer 2010) with 10 000 permutations to determine statistical significance. Based on previous mtDNA analysis (King et al. 2007) and intrinsic regional life history characteristics (e.g. migration, winter feeding areas), we determined the regional clustering of populations to avoid confounding hierarchical stratification in subsequent analyses. Thus, regional grouping among European populations was assessed first by calculating pairwise genetic distances using the \(D_A\) distance (Nei 1977). The resulting genetic distance...
Table 1 Description of regional groupings and parameters associated with sample sites composing the groups: latitude and longitude, number of individuals genotyped (\(N_{\text{GEN}}\)), number of individuals with call rate superior to 0.85 (\(N_{>85}\)), average call rate per population (CR) and average expected (\(H_E\)) and observed (\(H_O\)) heterozygosities per population

matrix was used to construct a neighbour-joining (N-J) phylogram, and confidence estimates on tree topology were obtained by re-sampling over loci with 1000 bootstrap replicates. The genetic distance estimation and bootstrapping procedures were carried out using POWERMARKER (Liu & Muse 2005). Based on the N-J tree (Fig. 2), European wild populations were clustered in three regional groups: Atlantic, Baltic Sea and Barents + White Seas (hereafter referred as Atlantic, Baltic and Barents–White). The composition of each subcontinental group is presented in Table 1. To confirm the relevance of hierarchical groupings (intercontinental and between regions within Europe), analyses of molecular variance (AMOVAs) were performed using ARLEQUIN 3.5. Seven North American populations were included mainly for estimating the overall divergence between continents, each of these having been chosen to represent one of the seven regional genetic groups defined by Dionne et al. (2008). A principal component approach was also used to identify the axes of greatest genetic differentiation between all populations. The principal components were constructed by decomposing the genomic relationship matrix among all individuals where the genomic relationship matrix was defined as in Yang et al. (2010). Principal components were fitted using R (R core development team).

**Outlier markers detection**

To identify the most divergent markers among populations, which may potentially comprise loci under divergent selection (but see Bierne et al. 2011), we used hierarchical Fdist (Excoffier et al. 2009), a genome scan analysis implemented in ARLEQUIN 3.5 (Excoffier & Lischer 2010). The finite island model that was used in Fdist has been shown to lead to large fraction of false positives in some systems; therefore, ARLEQUIN 3.5 proposes to use a hierarchical island model where migration rates among groups are different than migration rates among populations within groups. Thus, this hierarchical method can detect outlier loci among groups of populations ($F_{CT}$). In cases where no hierarchical structure was present, outliers were detected using $F_{ST}$, and therefore, the method was identical to the Fdist test of Beaumont & Nichols (1996).

Although regional groups were represented in North American samples, a regular Fdist was used because only one population per group was genotyped. Overall, five hierarchical tests were carried out, including an intercontinental comparison between anadromous European and North American populations, and one intra-Europe test contrasting the three regional groups defined (see Results section). Three additional hierarchical tests were performed to contrast landlocked and anadromous populations within each group (respectively, Atlantic anadromous: NUM, GAU and LAR; and landlocked: LL_NAM and LL_BYG; Baltic anadromous: KUN, VIN and TOR; and landlocked: LL_SYS and LL_PYA; and Barents anadromous: YAP, LEB, PON, EMT and SUM; and landlocked: LL_PIS) (See Table 1 for abbreviations definition). Hierarchical and nonhierarchical Fdist were run three times each in ARLEQUIN 3.5. Only loci detected as outliers at the significance level of 0.01 in all three runs were reported as potentially under the effect of selection. Outliers from each test were compared to examine possible parallelism between continents or between landlocked vs. anadromous populations from different regions. Evidence for parallelism would strengthen support for interpreting putative outliers as being under the effect of divergent selection.

**Candidate genomic regions affected by selection**

As an alternative to single-locus outlier tests, for European populations, we combined Atlantic salmon genetic map information (Lien et al. 2011) with a kernel-smoothing moving average approach (Hohenlohe et al. 2010) to generate genome-wide distributions of the divergence estimates (measured $F_{CT}$) from hierarchical and nonhierarchical Fdist (Excoffier et al. 2009). Only SNPs mapped

![Fig. 2 Genetic relationships in Atlantic salmon as resolved by neighbour-joining tree constructed using DA distance. Population code and numbers are as in Table 1 (populations with LL are landlocked). Nodes marked with a dot were supported by bootstrap support of <70% of 1000 replicates, and others are supported by more than 70% of 1000 replicates.]
by Lien et al. (2011) were used in this analysis. To identify genomic regions with an unexpectedly high proportion of SNPs showing increased or decreased divergence indicative of divergent and balancing selection, respectively, we performed 30,000–100,000 permutations to estimate local $P$-values. We tested multiple smoothing parameter values and selected 2 cm bandwidth that identified relatively narrow genomic regions of interest while being large enough to reduce sampling variance. For linkage groups (LGs) with relatively low SNP coverage, larger bandwidth (SSA08 = 5 cm; SSA26 = 4 cm; and SSA29 = 3 cm) was used. Despite the fact that the choice of bandwidth can have a strong effect on kernel density estimation, different smoothing parameters did not change the position of the major peaks (data not shown).

Gene ontology and SNP annotation

Blast2go (Gotz et al. 2008) was used to associate gene ontology (GO) annotation terms with all 6176 SNPs. Homology searching was first realized through a BLAST search of the available flanking sequences for each SNP on the NCBI nr public database with the $e$-value threshold set to $1 \times 10^{-10}$. Blast2go then retrieved GO terms associated with the obtained BLAST hits. The output GO annotation was then classified in multilevel biological processes, molecular functions and cellular components from the most general (level 2) terms of each category to more specific (upper levels) terms. In order to determine whether the biological processes, molecular functions or cellular components of the outliers herein identified were over-, equally or under-represented when compared to the 6176 analysed SNPs, we performed an enrichment analysis using Fisher’s exact test corrected for multiple tests by applying a false discovery rate (FDR) (Benjamini & Hochberg 1995).

Clinal variation among outliers

Because latitude is integrative of many correlated environmental variables along a South–North coastal line, we tested for the presence of latitudinal clines in allele frequency at outlier SNPs among European populations. Given that the allele frequency of many outlier markers (34 of 52) showed significant correlations with latitude (see Results), we visually compared the cline pattern at those markers with the 18 nonsignificant ones. When excluding the Barents–White populations from the regression analysis, we observed that the latter markers presented more significant cline patterns driven by shifts in Baltic populations. Therefore, instead of using latitude, we tested for clinal allelic frequency distribution using generalized linear models of coastal distances along two different continuia: (i) from northeastern populations to southern populations excluding the Baltic populations and (ii) using one of the Baltic population as the point of origin and measuring the distance away from this population excluding populations from the Barents–White group. For each continuum, respectively called the White–Barents and Baltic continua hereafter, we compared the outliers’ patterns with 52 randomly selected markers among the assumedly neutral (nonoutlier) markers (excluding European monomorphic markers). Finally, we used CFIT-6 (Gay et al. 2008) to test whether the observed clines presented a common centre or width. We thus compared four models: (i) no constraint, (ii) centre constrained, slope not constrained, (iii) centre not constrained, slope constrained and (iv) centre and slope constrained. Finally, outliers were positioned using the genetic map information from Lien et al. (2011).

Results

Genotyping and quality control

After initial quality control and classification of genotypes obtained from 1431 samples (Table 1; Fig. 1 for site locations), we classified (i) 5436 markers of 15 225 SNP features on the array as single-locus and polymorphic SNPs (i.e. diploid SNPs), (ii) 1725 markers as being represented at two homologous loci and polymorphic (i.e. MSV), (iii) 930 markers being represented at two homologous loci but displaying no polymorphism (i.e. PSV), (iv) 1853 failed assays and (v) 5281 nonpolymorphic markers (i–iv detailed in Lien et al. 2011). Mitochondrial SNPs were excluded from further analysis. Among diploid and MSV SNPs, 6112 markers showed an overall minor allele frequency (MAF) over 0.01. These, along with 64 other markers with an overall MAF < 0.01, but with a MAF > 0.05 in at least one population, made for a total of 6176 SNPs used in all analysis except stated otherwise. From the initial 1431 samples, 95 were discarded as they generated an average call rate <0.85 (proportion of SNPs genotyped), which was chosen as a threshold differentiating acceptable and unacceptable genotyping data. Table 1 shows summary data for call rates (CR), observed heterozygosity ($H_O$) and expected heterozygosity ($H_E$) across populations. A significantly higher overall observed heterozygosity (Wilcoxon’s rank sum test $P < 0.001$) for European compared to North American populations (0.241 and 0.148, respectively) indicated an ascertainment bias towards European populations or alternatively a naturally lower diversity in North American populations. This was anticipated as a large proportion of the SNPs on the array were detected by sequencing European aquaculture strains. GCR-derived

© 2012 Blackwell Publishing Ltd
markers were 2.4 times more heterozygous among European populations than among North Americans (average observed heterozygosity = 0.290 vs. 0.122). However, it should be noted that a few GCR markers were monomorphic across European populations. EST-derived markers, which should be less affected by ascertainment bias, were also more heterozygous in European samples albeit with a smaller difference (0.203 vs. 0.168) (Table S1, Supporting information). Pairwise $F_{ST}$ values were not significantly different between GCR- and EST-derived markers for comparisons of populations within Europe or within North American (respective Wilcoxon’s tests $P = 0.640$ and 0.881), but significantly different for intercontinental comparisons (mean $F_{ST}$: GCR = 0.463 and EST = 0.603; Wilcoxon’s $P < 0.001$). According to the Kolmogorov–Smirnov tests, within-region pooled population distribution of MAF showed that the Atlantic group had a significantly different distribution compared to all other groups ($P < 0.005$). The Baltic, North American and landlocked groups were similar to each other in MAF distribution. The Barents–White group presented a significantly different distribution from all other groups, while intermediate between the Atlantic groups and the others (Fig. 3).

Genetic diversity and population differentiation
With-in population observed and expected heterozygosities varied across populations and markers (Tables 1 and S2, Supporting information). North American populations showed lower observed heterozygosity (range: 0.123 NAR to 0.167 MAP) than European populations (range: 0.198 KUN to 0.303 TAN), while landlocked populations demonstrated the lowest values (0.104 LL_BYG to 0.170 LL_SYS). All samples showed similar observed and expected heterozygosities except for the Spanish Narcea population (NAC), which had higher observed heterozygosity than expected, probably due to stocking of genetically divergent non-native fish from northern European rivers (Ayllon et al. 2006). All pairwise comparisons of genetic differentiation between populations were highly significant ($P < 0.001$, Table S3, Supporting information). Overall, $F_{ST}$ varied between 0.011 (NES vs. DIO and NES vs. TWE) and 0.758 (NAR vs. LL_BYG). The within-Europe comparison varied between 0.011 and 0.347 (CAR vs. KUN), while within-North American $F_{ST}$ varied between 0.048 (CHA vs. MAP) and 0.151 (NAR vs. STP). Intercontinental differentiations along with intra-Europe landlocked comparisons showed the highest $F_{ST}$ with respective ranges of 0.439 (CHA vs. TUL and MAP vs. TUL) to 0.636 (CAR vs. NAR) and 0.320 (LL_PYA vs. LL_SYS) to 0.630 (LL_BYG vs. LL_NAM). An AMOVA considering both continents as regional groups and another carried out at the intra-Europe level considering the clusters identified previously with the phylogram as regional groups (Fig. 2) showed significant genetic variation among groups (Table 2). In the intercontinental analysis, 41% of variation was found among continental groupings (Europe and North America), while within Europe, 7.55% of variation was found among regional groupings (Atlantic, Baltic and Barents–White). In a principal component analysis (PC) of the genomic relationships among individuals, seven PC factors individually determined at least 1% of variation and together explained 55.1% of the total genetic variation among populations. Principal components 1–4 accounted for 38.4%, 9%, 2.1% and 1.7%, respectively. PC1, PC2 and PC3 differentiated the European populations from the North American populations (Fig. 4a), while PC3 separated the populations within Europe almost along a northeast–southwest axis, with Spanish populations at one end and most Russian populations and Baltic populations at the other end (Fig. 4b).

Outlier markers detection
Six genome scans (Fig. 5) were performed using 6176 SNPs with a varying number of markers potentially under divergent (range between 26 and 139) and balancing selection (range between 20 and 101) at the 0.01 significance level (Table S4, Supporting information). The hierarchical genome scan performed over all anadromous populations revealed the highest number of loci potentially under divergent selection (139) while also yielding the lowest number of markers potentially under balancing selection (20) in spite of an average $F_{CT}$ across loci of 0.311 (ranging from $–0.055$ to $0.997$). European (mean $F_{CT} = 0.063$; ranging from $–0.052$ to 0.732) and North American (mean $F_{CT} = 0.081$; ranging from $–0.024$ to 0.780) genome scans showed similar numbers of potentially selected loci with, respectively, 52 and 51 divergent outliers and 61 and 46 markers under balancing selection. Four outliers were common to both European and North American genome scans. Three showed similar trends as two were detected as potentially under divergent selection (ESTNV_28701_207 and ESTNV_23580_687) and one under balancing selection (ESTNV_28516_389). However, one showed opposite trends (ESTNV_32552_113) as it was potentially under divergent selection in the European scan and under balancing selection in the North American scan.

All three hierarchical genome scans also revealed SNPs under potential divergent and balancing selection when anadromous populations were compared with landlocked populations from the same geographical
region (respectively, N divergent = 40, 49 and 40; N balancing = 31, 41 and 38; mean $F_{CT} = 0.057, 0.060$ and 0.100; maximal values 0.876, 0.883 and 0.983). Three outliers were common to landlocked vs. anadromous genome scans. Marker ESTNV_33891_846 was found to be under balancing selection among Barents–White and Baltic populations, GCR_cBin31530_Ctg1_84 under balancing selection among Baltic populations while under divergent selection in the Atlantic populations and GCR_cBin14325_Ctg1_429 was under divergent selection in Barents–White and Atlantic populations. None were common to all three genome scans.

Candidate genomic regions affected by selection

To further gain insight into the chromosomal patterns of divergence (measured as $F_{CT}$) along the mapped linkage groups, we identified genomic regions showing...
unexpectedly high or low divergence between different European regional groups. Altogether, 19 genomic regions showed increased differentiation ($P < 0.01$) in European comparisons (Fig. 6a; Table S5, Supporting information). A slightly larger number of genomic regions ($n = 25$) exhibited reduced levels of differentiation ($P < 0.01$) (Fig. 6a; Table S5, Supporting information). When compared with the single-locus outlier tests, both analyses often revealed similar candidate regions potentially under divergent selection (Figs S1–S29, Supporting information e.g. LG: SSA01, SSA05, SSA10, SSA12, SSA15-SSA17, SSA18, SSA20). The strongest evidence ($P < 10^{-5}$) for increased or reduced differentiation was found in LG SSA08 and SSA16 (Fig. 6bc).

**Annotation of outlier SNPs**

The BLAST (Altschul et al. 1990) yielded 2691 SNPs with significant hits ($e$-value $< 1 \times 10^{-10}$, Table S6, Supporting information). From these results, a total of 17 701 GO terms were associated with SNPs. GO terms segregated into many levels of biological processes,
molecular functions and cellular components with a mean level of 5.819. Overall, 19-level 2 biological pathways associated with cellular process, metabolic process and biological regulation were highlighted, and together, these represented 48% of GO annotations. After correction for multiple testing, an enrichment analysis across both categories of outliers (divergent and balancing) did not indicate significant over- or under-representation of any biological pathway in the outliers identified. Among common outliers in European vs. North American comparison, ESTNV_28701_207 (potentially under divergent selection) was associated with a B-cell receptor (CD22-like), which prevents overactivation of the immune system (Hatta et al. 1999), while marker ESTNV_32552_113 (divergent in Europe, balancing in North America) has a close relationship with a calcium ion–binding protein. Common outliers among anadromous and landlocked populations revealed one marker, ESTNV_33891_846 (under balancing selection in Barents–White and Baltic), which has an association with coagulation factor V.

**Clinal variation among outliers**

Among the 52 outliers potentially under divergent selection among all anadromous European populations, the population allelic frequencies of 34 markers were significantly correlated with latitude ($R^2$ ranging from 0.177 to 0.498, mean = 0.308). The generalized linear models applied to each of two different continuums, one starting in White Sea (excluding the Baltic) and the other in the Baltic Sea, revealed that 23 and 18 outliers present only in the White–Barents and Baltic continua, respectively, and 11 outliers showing clinal patterns common to both continua. Therefore, all 52 markers showed a clinal pattern for one or both continuia. The congruence of outlier markers was striking when contrasted with randomly selected neutral markers (Fig. 7). In both continua, the model with no constraint was always the best one (Table S7, Supporting information), meaning that there was no common centre or width associated with observed clines. However, the average

© 2012 Blackwell Publishing Ltd
localizations of the centres were 1092 and 1009 km from the point of origin for the White Sea and Baltic continua, respectively. These averages closely coincide with the boundaries between the Barents Sea vs. Atlantic and Baltic Sea vs. Atlantic. This also closely matches the genetic boundaries inferred from the three genetic groupings defined earlier. Finally, the outliers showed a random distribution on the genetic map with no apparent clustering on specific linkage groups (Fig. 8).

Discussion

This study represents the single most extensive population genetic study on Atlantic salmon performed to date. With 1360 individuals successfully genotyped for over 6000 SNP markers, it also stands as one of the most comprehensive population genetics studies of wild populations in a nonmodel species. An important outcome of our study, particularly for population management, is the robust confirmation of three major regional genetic groups occurring in Europe. Moreover, based on strong clinal patterns observed for identified outlier markers, we propose that these groups are bordered by secondary contact zones where highly divergent markers are associated with endogenous (intrinsic genetic incompatibilities) and possibly exogenous (environmental or ecological) barriers (Bierne et al. 2011).

Ascertainment bias

Among the 6176 SNPs retained on the SNP array, 3383 were detected from available EST reads from both European and Canadian materials. On the other hand, the GCR markers were discovered using only Norwegian commercial aquaculture fish, meaning that these markers are potentially more prone to an eastern Atlantic European bias when used for genotyping more geographically dispersed samples. The sampling bias towards the Atlantic populations and to a lesser extent in the Barents–White groups could potentially bias our differentiation estimates. Indeed, Albrechtsen et al. (2010) observed a small upward bias in $F_{ST}$ estimates using ascertained populations. They also showed that the intensity of the bias depends on the genetic distance of the populations being compared relative to the population within which the markers were originally developed, suggesting that $F_{ST}$, when two populations outside of the ascertained regional group are compared to each other, may be less affected by ascertainment bias.

A significantly higher genetic diversity ($H_O$) in European samples was observed for both EST- and GCR-based markers (Table S1, Supporting information). Contrasting estimates of genetic diversity between the continents are partly explained by the ascertainment bias.
bias and are of concern for estimating and interpreting other genetic parameters. Indeed, we found that intercontinental population differentiations are significantly higher when measured with EST-based markers than with GCR-based markers. Therefore, this bias should be taken into consideration in any intercontinental comparisons using the array. That said, it is noteworthy that in a survey of microsatellite diversity, King et al. (2001) also found that genetic diversity was reduced in North American populations compared with European populations using markers developed with material from both origins. It is thus possible that different demographic history partly explains the overall differences in genetic diversity between continents.

In contrast, no significant difference in intracontinental population differentiation was observed when estimates

---

Fig. 7 Generalized linear models illustrating latitudinal clines (or lack thereof) for 52 European outliers (left panels) and 52 randomly selected neutral (nonoutlier) markers (right panels) shown along two different coastal distance continuum: (a) the Baltic and (b) the White-Barents.

Fig. 8 European regional differentiation ($F_{CT}$) of each single nucleotide polymorphism marker mapped on the European Atlantic salmon genetic map. Grey and white rectangles separated by vertical dashed lines represent separate linkage groups (named SSA–). Large black dots indicate outlier markers, and the horizontal dotted line indicates the average $F_{CT}$ among markers (0.063).
were calculated with EST and GCR markers separately (data not shown). However, within Europe, genetic diversity is also regionally heterogeneous with lower genetic diversity associated with Baltic and landlocked populations. Here again, this regional pattern of variation was observed in previous studies using microsatellites and was attributed to the phylogeographic history of these populations (Säisaä et al. 2005; Tonteri et al. 2007). Overall then, it appears that variation in genetic diversity between regions results from both historical contingency and ascertainment bias. We thus advise that absolute values in intercontinental comparisons should be interpreted carefully. However, the bias effect is less of a concern for within continental comparisons, especially for interpreting broad-scale patterns of differentiation.

**Population structure**

While Atlantic salmon population structure has been extensively investigated (Stålhl 1987; King et al. 2001; Verspoor et al. 2005; Dionne et al. 2008), this study is the first to examine the structure of population over its entire range with extensive genomic coverage in a single original study. Overall, the results provided by the SNP markers show similar patterns as those previously observed, but the level of differentiation is amplified with $F_{ST}$ values up to twice as high as previously reported, may be due to the lower level of polymorphism in SNPs compared to microsatellites (Hedrick 1999). As an example, a within-continent comparison of pairwise $F_{ST}$, Dionne et al. (2008) reported a $F_{ST}$ value of 0.048 based on 12 microsatellites, compared to the value of 0.112 we observed with SNPs for the same comparisons. This enhanced structure definition is observed on every scale examined. Indeed, the range-wide analysis suggested that 41% of the genetic variation occurred between the continents, which contrasts with the 21.9% reported by King et al. (2001). Although we did not observe any continent-specific alleles as previously observed for microsatellite markers (King et al. 2001; Wennevik et al. 2004), we did identify over 100 SNP markers with $F_{CT} > 0.95$, that is, nearly diagnostic between continents.

Following the pioneering study of Stahl (1987) who first identified two distinct genetic groups of Atlantic salmon within Europe, namely Eastern Atlantic and Baltic Sea, many studies subsequently focused on the colonization history of northern Europe following the last ice age and its impact on regional genetic groupings of Atlantic salmon populations (Kazakov & Titov 1991; Skaala et al. 1998; Koljonen 2001; Wennevik et al. 2004; Makhrov et al. 2005; Saisa et al. 2005; Tonteri et al. 2005). Most of these studies were congruent in differentiating the Baltic Sea populations and regrouping other populations into an Atlantic + Barents Sea + White Sea group. Verspoor et al. (2005) reported that more groups could be defined in Europe, especially within the previously named Atlantic group. More recently, Tonteri et al. (2009) demonstrated the genetic distinctiveness of the Eastern Barents Sea and White Sea populations from the Western Barents and Eastern Atlantic ones. Our results confirm this partitioning of northern populations and further suggest the contribution of at least three glacial refugia in colonizing European populations. Essentially, we observed three major clusters corresponding to an Atlantic group, a Baltic Sea group and a Barents–White Sea group. A relatively high proportion (7.55%) of the genetic variation occurred among these groups, although a higher proportion (10.4%) was also attributed to differences among populations within each of them. These three groups are consistent with the main postglacial colonization routes previously identified as the West Atlantic, the Baltic Ice Lake and Eastern Barents Sea (Tonteri et al. 2007, 2009; and references therein).

Landlocked populations exhibited a structure also consistent with previous studies. However, this study allowed a finer understanding regarding the origins of these populations from anadromous ancestors. Tonteri et al. (2005) suggested that freshwater populations from the Baltic and White Sea basins originated from different populations, explaining their segregation into two different clusters based on 14 microsatellite markers. Here, we observed approximately 1.5 times more differentiation when contrasting landlocked populations from these two basins with any anadromous populations of their respective basins. Additionally, freshwater Baltic populations clearly clustered with anadromous Baltic populations, while the nonanadromous population from the White Sea basin clustered with the Barents–White group. Based on their geographical location, Norwegian populations were expected to cluster as Atlantic populations, but showed a high degree of divergence from all three regional genetic groups. Because their closest neighbours on the tree are Norwegian or Western European populations, it is highly possible that their differentiation from the Atlantic group stems from a very pronounced drift effect resulting from a founder event, which could have occurred during land upheaval following the last deglaciation in Norway (Berg 1985).

**Signatures of selection**

The detection of loci under selection using different genetic differentiation methods shares several known caveats, particularly the potential for false positives with such a high degree of multiple testing (Foll &
Gaggiotti 2008). Nonetheless, these methods have been successfully used for identifying candidate genes and QTL for local adaptation to environmental conditions (Schmidt et al. 2008; Storz & Wheat 2010; Gagnaire et al. 2012b), localizing genomic regions under adaptive divergence (Rogers & Bernatchez 2007; Flori et al. 2009; Hohenlohe et al. 2010; Gagnaire et al. 2012a) or identifying markers to investigate introgression (Hohenlohe et al. 2011; Karlsson et al. 2011; Lamaze et al. 2012). While a main objective of this study was to assess the extent of potential adaptive divergence among populations throughout the native range of Atlantic salmon, we were not able, in some comparisons, to distinguish the effect of selection from that of pronounced drift. In other comparisons, using multiple populations subject to the same putative selection reduced the chance that the outliers identified were mainly the result of drift.

Markers identified as outliers when contrasting genetic variation on both continents genetic compositions were almost differentially fixed within each continent. Given the estimated time of 600 000 years since continental interdivergence (King et al. 2007) and very modest contemporary migration rates between the two continental lineages, we were expecting many more strictly differentially fixed markers than were observed. Thus, the absence of fixed markers could mean that the migration rate between both lineages was previously underestimated. However, we cannot exclude that ascertainment bias, the method of SNP selection and the unbalanced coverage of genetic variation towards Europe might also contribute to this pattern.

Although environmental gradients occur along the geographical distribution of Atlantic salmon, contrasting the three major clusters identified failed to isolate markers that could be strictly under the influence of environmental selection. Instead, our results revealed that the majority of outlier markers showed allele frequencies that correlated with geographical clines (compared to nonoutlier markers) in both the Baltic vs. Atlantic and Barents–White vs. Atlantic comparisons. This could be a result of historical colonization and persisting tension zones following secondary contact between once geographically isolated lineages. We did not identify a common centre or width for these clinal outliers (Table S7, Supporting information). However, all markers showing clinal variation were strictly outliers, they showed an overall congruence in geographical patterns of variation (Fig. 7), and that they were randomly distributed in the genome (Figs 6 and 8). This strongly suggests that these markers are likely to reveal endogenous genetic barriers (genetic incompatibilities) occurring in zones of secondary contact between distinct evolutionary lineages, rather than genetic–environment associations (exogenous barriers). As demonstrated by Bierne et al. (2011), endogenous genetic barriers can easily be coupled with exogenous genetic barriers associated with environmental gradients. Here, environmentally driven selection could be responsible for some of the observed clines since environmental heterogeneity, mainly in terms of temperature, and salinity also occurs along these zones. However, our data and analysis do not allow us to tease apart markers potentially under the influence of environmental selection vs. others. For instance, the Öresund and Danish Belts delimit an important environmental discontinuity between the Baltic Sea and the Atlantic Coast characterized by an abrupt change in salinity (among other parameters) that have been identified as a selective agent in many species (Johannesson & Andre 2006; Gaggiotti et al. 2009; Lomborg et al. 2009). Here, we found that this geographical region is associated with numerous outlier markers showing clinal variation. We do not challenge the environmental selection acting in this area and certainly acknowledge previous studies identifying this possible hotspot for genetic–environment associations. However, our results suggest that careful interpretation of outlier markers is needed, especially in known secondary contact zones. Namely, as it is likely the case for the Baltic, hybrid zone theory predicts that tension zones will be trapped by natural barriers (Barton 1979; Barton & Hewitt 1985; Hewitt 1988; Bierne et al. 2011). Should this be the case in the Barents Sea as well, characterization of the putative environmental barrier operating there might reveal possible functional targets of selection. Overall, we emphasize that identifying genomic regions underlying a true genetic–environment association first needs functional support and/or convincing rejection of historical contingency on top of detailed environmental characterization. Therefore, in the case of Atlantic salmon, we suggest that future research should focus on disentangling the interplay between historical and selective forces.

As for the North American populations analysed in this study, only cautious interpretations can be drawn given that results are still equivocal. Previous studies of Western Atlantic salmon provided evidence for a hierarchical genetic structure. However, depending on the markers used and geographical coverage, defined regional groups differed among studies (King et al. 2007 and references therein; Dionne et al. 2008). Interestingly, there is evidence that North America was colonized by at least two major refuges given the presence of European mtDNA haplotypes in many landlocked populations (Knox et al. 2002; King et al. 2007). Nonetheless, the regional structure of anadromous populations was never associated with postglacial colonization from multiple source populations, as in Europe. Instead, recent landscape genetics studies have shown that regional differences are likely driven by distinct environmental conditions, which would imply a regional scale of local adaptation (Dionne
et al. 2007, 2008), which may be more common in anadromous salmonids than previously thought (Fraser et al. 2011). In this context, we argue that identified outliers could represent or be associated with actual targets of environmental selection. However, the limited coverage of North American populations hampered the possibility to pinpoint any specific biological function or process among annotated outliers that could have established potentially functional targets of selection and thus useful candidate genes. Clearly, further investigation of adaptive divergence among North American populations will necessitate deeper sampling coverage within and among regional groups along with a detailed landscape genomics approach.

Contrasting landlocked versus anadromous populations in Europe identified markers that were strikingly differentiated between the two life history strategies. Such differences may indicate ecological selection and/or random genetic difference due to genetic drift. None of the outliers that were detected showed parallel patterns of divergence among the three regional genome scans we performed. However, we found three markers identified as outliers in two of three scans. Although all three showed different patterns (divergent selection in one group, balancing selection in opposite directions in the other groups), and only one was successfully annotated, these exploratory scans suggest that there is sufficient divergence between landlocked and anadromous populations to justify further examination. We propose three main steps to undertake in a follow-up study that would aim specifically at elucidating the adaptive divergence between these populations. First, comparing regional replicates holds the key to distinguishing selection from drift. Second, a less stringent significance threshold could be used to detect outliers in order to allow more markers to be further examined and screened using ecological and functional context. Finally, particular attention should be paid to candidate genes involved in osmoregulation and immune-related functions that are possible targets for selection given the contrasting environmental conditions encountered by anadromous and landlocked populations. The upcoming genome sequence (Davidson et al. 2010) of Atlantic salmon promises to improve the functional context and further contribute to disentangling historical from adaptive divergence.

Implications and perspectives

In addition to the recent demographic decline of most anadromous populations, related concerns such as the relative genetic contribution of individual populations to fisheries or bycatch, translocation, reintroduction strategies and assessments of farmed escapees’ impacts are all management issues that could benefit from the improved genetic information derived from the SNP array. Information from the array allows finer, more precise definition of populations, management and ESU. In this study, using the SNP array certainly enhanced the resolution of such units by revealing increased level of differentiation estimates at every geographical scale relative to previous studies. Our study suggests that escapees from aquaculture (the majority of which stem from Norwegian aquaculture populations of the Atlantic group in Europe) could lead to different genetic consequences whether introgressing into wild populations of the same (Atlantic) or different (Barents–White) phylogeographical groupings. The array should contribute in resolving the continuing controversy surrounding the potential impacts and level of introgression of captive bred fish in wild populations. For instance, the SNP array developed here has recently been used by Karlsson et al. (2011) to develop a subpanel of markers that can discriminate between wild populations and the major strains of domestic Atlantic salmon used for farming in Europe, enabling the assessment of the impacts of farmed escapees on wild populations. Furthermore, linking genetic and environmental divergence could highlight biological processes that evolve under the effect of natural selection and identify the actual selective agents. Although further investigation is needed to delineate the relative contribution of adaptive divergence in observed patterns of genetic differentiation, the ubiquitous occurrence of highly divergent markers representing a diversity of biological functions holds the potential for adding information about the adaptive nature of divergence in defining significant units of management and conservation. Being aware of historical contingency effect on observed patterns of differentiation, we are now better suited to grasp the real contribution of environmental selection in shaping population divergence in Atlantic salmon. Overall then, this SNP array and subsequent versions of it should bring considerable benefits to Atlantic salmon management and conservation community as well as for aquaculture applications.

Acknowledgements

We are grateful to Eva Garcia-Vasquez, Jamie Stevens, Sigurdur Gudjonsson, Melanie Dionne, Alexei Veselov, Jaakko Lumme, Jan Nilsson and Jaakko Erkinoarvi for providing samples. The SNP discovery, array development and genotyping were performed by CIGENE at the national technology platform, supported by the functional genomics programme (FUGE) in the Research Council of Norway. We also thank P.A. Gagnaire, Gonzalo Machado-Schiaffino and M. Bruneaux for their very constructive inputs in the signature of selection analysis and interpretation. A special thanks to Ben J. Hayes for his regular
inputs to the manuscript and analyses. Research was supported by grants from the Natural Sciences and Engineering Research Council of Canada (NSERC) to VB, from the Canadian Research Chair in genomics and conservation of aquatic resources to LB, the Academy of Finland to CRP and AV, Estonian Science Foundation to AV and the Beaufort Marine Research Award in Fish Population Genetics funded by the Irish Government under the Sea Change Programme to PMcG.

V.B. is currently studying the genomic basis of adaptive divergence and sea mortality of Atlantic salmon as a Ph.D. candidate under the supervision of L.B. His main interests are in population, landscape and conservation genomics. M.P.K.’s research interest revolves around use of next-generation sequencing tools and data analysis for SNP discovery and genome assembly in non-model organisms, and the subsequent development of high-density SNP arrays and critical analysis and interpretation of raw SNP data. C.R.P.’s research aims to understand the genetic processes underlying adaptation in salmonid fishes. A.V. is interested in understanding patterns of genetic and phenotypic variation in natural fish populations using ecological genomic tools. S.K.’s research interests are in population genetics of aquatic species and interactions between farmed and wild Atlantic salmon. K.H.’s research interests are to understand the genetic and ecological structuring of salmonid fishes, and how human activities affect this structuring. P. M.C.G.’s research interests are in the areas of evolutionary biology, population genetics and ecology of fish, in particular the study of Atlantic salmon. He has a specific interest on the impact on local populations of introducing captive bred fish.
into the wild. E.V.’s main interest is the application of genetics to the management of freshwater biodiversity with a particular interest in the evolution of population structuring Atlantic salmon and other salmonid fishes. L.B.’s research focuses on understanding the patterns and processes of molecular and organismal evolution as well as their significance to conservation. S.L.’s scientific interests are the mapping and molecular dissection of complex traits in cattle, pig, salmon, cod and wheat, as well as studying the mechanisms of rediploidization in salmonids.
